5

Autologous Self-Tolerance Inducing Cells of Monocytic Origin and their Use in Pharmaceutical Preparations

10

The invention relates to autologous cells of monocytic origin, which are capable of inducing immunologic self-tolerance in a patient. These cells are subsequently designated "STIC" (self-tolerance inducing cells). The invention further relates to

15   the use of STIC in pharmaceutical preparations for the preven-tion and/or treatment of diseases associated with disturbed self-tolerance, as in particular autoimmune diseases and al-lergies.

20   In relation to the invention the term "autologous" indicates that the STIC are derived from monocytes from the blood of the respective patient to whom the STIC are to be administered.

It has been shown by the inventors that the cells of the in-
25   vention are capable of inducing regulatory T-cells ($Treg_{CD4+25+}$).
The invention therefore also relates to the induction and/or *in vitro* preparation of regulatory T-cells.

The immune system protects the body from potentially patho-genic antigens, as for instance microorganisms, while it nor-
30   mally avoids reacting with constituents of the body itself; i.e. the healthy immune system tolerates "self antigens".

Disturbed self-tolerance occurs when specific adaptive (ac-
35   quired) immune responses are mounted against self antigens.

2

The normal consequence of an adaptive immune response against the foreign antigen is the clearance of the antigen from the body. When an adaptive immune response develops against self antigens, it is, however, usually impossible for immune effec-

5   tor mechanisms to eliminate the antigen completely and so a sustained response occurs. The consequence is that the effector pathways of immunity cause chronic inflammatory injury to tissues, which may prove lethal (see Immuno Biology 5, The Immune System In Health and Disease, Garland Publishing 2001,

10   Chapter 13, pages 501-522).

Adaptive immune responses are initiated by the activation of antigen-specific T and/or B cells, and it is believed that autoimmunity is initiated the same way (Immuno Biology,

15   loc.cit. p. 501).

One preferred embodiment of the invention relates to the treatment and/or prevention of autoimmune diseases using pharmaceutical preparations containing STIC.

20

Two major patterns of autoimmune diseases may be distinguished. Diseases, in which the manifestation of autoimmunity is restricted to specific organs of the body, are known as "organ-specific" autoimmune diseases, while, in "systemic"

25   autoimmune diseases, many tissues of the body are affected. Examples of organ-specific autoimmune diseases are Hashimoto's thyroiditis and Graves' disease, which each predominantly affect the thyroid gland, and Type I insulin-dependent diabetes mellitus, which affects the pancreatic islets. Examples of

30   systemic autoimmune diseases are systemic lupus erythematosus and primary Sjögren's syndrome, in which tissues as diverse as the skin, kidneys, and brain may all be affected (see Immuno Biology, loc.cit, page 503).

3

There are autoimmune diseases, which are primarily believed to be T cell-mediated, as for instance insulin-dependent diabetes mellitus, rheumatoid arthritis, and multiple sclerosis, while, in other cases, the formation of antibodies to cell surface or
5   matrix antigens plays a dominant role, as for example in auto-immune hemolytic anaemia, autoimmune thrombocytopenic purpura, Goodpasture's syndrome, pemphigus vulgaris or acute rheumatic fever; a still other group are immune-complex diseases, wherein both T cells and B cells are involved, as for instance
10   mixed essential cyroglobulinemia, systemic lupus erythematosus or rheumatoid arthritis (see Immuno Biology, loc.cit, Fig. 13.1 on page 502).

A further embodiment of the invention relates to the treatment
15   of allergies with the STIC of the invention formulated as pharmaceutical preparations.

It has recently been suggested that regulatory T-cells play an important role in controlling immune homeostasis, that is, an
20   orchestrated immune response to any infectious or antigen re-lated target including immunologic self-tolerance, see Takeshi Takahashi and Shimon Sakaguchi, International Review of Cytol-ogy, **225**, 1-32 (2003); Shimon Sakaguchi, Vox Sang **83**, 151-153 (2002), Kathryn J. Wood and Shimon Sakaguchi, Nature Reviews
25   Immunology, **3**. 199-210 (2003).

As stated by Takahashi et al., loc.cit. page 1, Abstract, "Ac-cumulating evidence indicated that T cell-mediated dominant control of self-reactive T cells contributes to the mainte-
30   nance of immunologic self-tolerance and its alternation may lead to development of autoimmune disease. Efforts to deline-ate such regulatory T cell populations have revealed that CD 25^+ cells within the $CD4^+$ population in normal naive animals including humans possess the regulatory activity. The $CD25^+$

plus CD4$^+$ regulatory T cells are produced by the normal thymus as a functionally distinct subpopulation of T cells. They play critical roles not only in preventing autoimmunity but also in controlling various immune reactions".

In addition to T cell mediated autoimmune diseases, the B cell compartment of the immune system can trigger autoaggressive diseases associated with the production of antibodies directed against self cells (including mast cells), tissue and organ structures.

It is well known that B cell activation depends on T cell help in such a way that T helper cells stimulate clonal B cell expansion upon presentation of specific antigens. Those antigens may be derived from fragmented allergens and are then processed within the T cell to small molecule peptides. These are then presented in a MHC-restricted fashion in order to stimulate antigen-specific activation.

In order to prevent uncontrolled or excessive B cell activation caused by specific allergens which leads to allergic diseases on the one hand and which can induce disturbed self-tolerance on the other hand (see above), regulatory T cells have the capacity to interfere with T cell associated B cell activation and prevent excessive and uncontrolled antibody production.

Similar to autoimmune diseases, also allergic diseases can therefore be influenced and controlled by increasing the amount of regulatory T cells (CD4$^+$/CD25$^+$ T cells). In particular, it has been shown in mice suffering from EAE ("experimental allergic encephalomyelitis") that the disease remits a couple of weeks after CD4$^+$ T cells have been administered to these animals, and that the cure is associated with resistance

5

to any further disease induction (Bach, J.F. "Regulatory T Cells under Scrutiny" Nature Reviews Immunology **3**: 189-198 (2003); Lando, Z. et al. "Effect of cyclophosphamide on sup-pressor-cell activity in mice unresponsive to EAE" J. Immunol.

5   **123**: 21556-2160 (1979)). These effects are similar to those shown for NOD mice in which the progression of autoimmune dia-betes can be stopped by administration of $CD4^+$ cells, further leading to protection of the mice against new outbreaks of the autoimmune disease (Bach, J.F., *loc.cit.*).

10

Examples for allergic diseases, which may be associated with autoimmune reactions are all types of allergies induced by non-self proteins, organic and inorganic substances encounter-ing the body. Of particular importance in this regard are al-

15   lergies induced by pollen like e.g. hayfever and allergies in-duced by allergens like drugs, chemicals, viruses, bacteria, fungi, house dust, food components, metals, gas, body compo-nents of animals such as skin scale or hair, and animal ex-creta.

20

To date no effective therapeutics are available for the pre-vention and/or treatment of diseases resulting from disturbed self-tolerance.

25   With respect to organ specific autoimmune diseases, substitu-tion treatment, transplantation or symptomatic treatment with antiinflammatory agents like cortisone are usually applied. With respect to systemic autoimmune diseases, immuno suppres-sive agents are often used for treatment. Clearly these

30   "therapies" are problematic in many respects and suffer from serious side effects.

It is estimated that up to 5% of the population are afflicted by autoimmune diseases (Sakagushi, loc.cit., page 151, left

column). Therefore, an urgent need exists for effective means for the prevention and/or treatment of diseases associated with disturbed self-tolerance which are easy to handle and which are not associated with the health threatening side ef-

5 fects and the high costs involved with the methods and agents to date applied in the treatment of such diseases.

It is therefore the problem underlying the invention to pro- vide improved means for preventing and/or treating diseases

10 associated with disturbed self-tolerance.

For the solution of the problem, the use of autologous self- tolerance inducing cells (STIC) of monocytic origin from ver- tebrates, in particular from mammals and more preferred from

15 humans is proposed. These cells are obtainable by the process of the invention described below, which process results in modified cells, capable of increasing the amount of regulatory T-lymphocytes (CD4$^+$/CD25$^+$ T-cells) in the body of an individ- ual. After administration of approximately 10^5 cells/kg body

20 weight(BW), these cells are suitable for preventing and/or treating diseases associated with disturbed self-tolerance.

25   Description of the Figures

Figure 1:   Flow cytometric determination of the binding ca- pacity of GM-7 to original monocytic cells before (graph on the left hand side) and after (graph on

30.   the right hand side) modification of the cells according to the invention. The x axis indicates the number of bound cells.

              phocytes (PhaLy) and TAIC ("Mo+Ly" or "Mo"),
              preincubated in two experiments with an inhibi-
              tor (1-MT) of indolamine-2,3-dioxygenase (IDO)
              for determining the influence of 1-MT on the
              suppressor activity of the TAIC.

Figure 5:   Flow cytometric determination of GM-7-expression
              in the blood of patients postoperatively prior
              (left Figure) and after (right Figure) injection
              of TAIC, for determining the influence of TAIC
              on the *in vivo*-GM-7-expression in blood cells.

Figure 6:   H&E staining of colon sections of mice suffering
              from dextran sulphate sodium (DSS)-induced
              chronic colitis illustrating the condition of
              the colon of an untreated animal of group 3
              (Fig. 6A/B), an animal of group 1 treated with

STIC on day +1 following the DSS treatment (Fig. 6C/D), an animal of group 4 treated with "control cells" at day +1 (Fig. 6E) and of an animal treated with STIC at day +7 (Fig. 6F). (magnification × 2,5 in Fig. 6A/C/E; magnification × 10 in Fig. 6B/D/F)

Figure 7:   Changes in the body weight of mice suffering from dextran sulphate sodium (DSS)-induced chronic colitis in the course of a 3 week period after the end of the DSS treatment. Animals of group 1 (■) have been treated with STIC at day +1, animals of group 2 (▲) have been treated with STIC at day +7, animals of group 3 (▼) have been untreated, while animals of group 4 (●) have been treated with "control cells" at day +1. The values are mean values obtained from 5 to 7 mice per group, the standard deviation is always below ± 15 %.

Figure 8:   Results of the scoring of histochemically stained colon sections of mice suffering from dextran sulphate sodium (DSS)-induced chronic colitis. Animals of group 1 have been treated with STIC at day +1, animals of group 2 have been treated with STIC at day +7, animals of group 3 have been untreated, while animals of group 4 have been treated with "control cells" at day +1. (score 0 = healthy unobtrusive finding; score 1 = minimal colitis; score 2 = moderate colitis; score 3 = heavy colitis; and score 4 = ulcerative colitis accompanied by destruction of the whole mucosa).

Figure 9:   Changes in the body weight of mice of the
              CD62L$^+$/CD4$^+$ SCID transfer model of chronic experi-
              mental colitis with reference to the weight of
5   the mice 6 weeks after the beginning of the ex-
              periment when they receive the cell therapy. Ani-
              mals of group 1 (♦) have been treated with STIC
              after 6 weeks, animals of group 2 (■) have been
              untreated and animals of group 3 (▲) have been
10   treated with "control cells" after 6 weeks. The
              values are mean values obtained from 6 mice per
              group, the standard deviation is always below ±
              15 %.

              of mice of the CD62L$^+$/CD4$^+$ SCID transfer model of
25   chronic experimental colitis six weeks after cell
              transfer. Animals of group 1 have received STIC,
              animals of group 2 have been untreated and have
              received no cell injection, while animals of
              group 3 have received "control cells". The val-
30   ues are mean values ± SEM. (score 0 = healthy un-
              obtrusive finding; score 1 = minimal colitis;
              score 2 = moderate colitis; score 3 = heavy coli-

10

tis; and score 4 = ulcerative colitis accompanied by destruction of the whole mucosa).

5   Figure 12:   H&E staining of colon sections of mice of the CD62L$^+$/CD4$^+$ SCID transfer model of chronic experimental colitis illustrating the condition of the colon of two untreated animals of group 2 (Fig. 12A/B), of two animals of group 3 treated with "control cells" (Fig. 12C/D) and of two 10   animals of group 1 treated with STIC (Fig. 12E/F). (magnification × 100)

15   **Summary of the invention**

The basic steps of the process for preparing autologous self-tolerance inducing cells (STIC) of monocytic origin comprise:

20   (a)   Isolating monocytes from the blood of the respective patient to whom the cells are to be administered;

(b)   Propagating the monocytes in a suitable culture medium which contains the macrophage colony stimulating fac-25   tor (hereinafter referred to as M-CSF) as growth promoting agent;

(c)   Stimulating the monocytes with γ-interferon (hereinafter called γ-IFN); and

30
(d)   Obtaining the self-tolerance inducing cells formed in stage c) by separating the cells from the culture medium.

A similar process is described in the German Patent Application DE 102 31 655.4 and in the International Patent application PCT/EP03/07551. In the aforementioned earlier patent ap-
5   plications the cells so prepared are designated "transplant acceptance inducing cells" (TAIC). They are used for inducing acceptance of allogeneic donor tissue in the recipient. Impor-tantly, the TAIC described in DE 102 31 655.4 and in PCT/EP03/07551 are derived from monocytes of the donor and are
10 administered to the recipient in order to induce transplant acceptance. This means that the TAIC are allogeneic to the in-dividual to be treated with the TAIC.

In contrast, the present invention is based on the concept of
15 "autologous treatment"; this means that an individual suffer-ing from disturbed self-tolerance, in particular from autoim-mune diseases and/or allergies is treated with self-tolerance inducing cells (STIC), which are derived from autologous mono-cytes.
20
Therefore, while TAIC and STIC are both derived from monocytes by essentially the same process, TAIC are allogeneic to the patient to be treated, while STIC are autologous in this re-spect.
25
With respect to the process for producing STIC it has been shown that the stimulation with γ-IFN represents a decisive step (see Example 2).

30 In the context of the present invention, the term self-tolerance inducing cells (STIC) of monocytic origin desig-nates the cell population, which is obtained from step (d) of the process described above. This cell population comprises next to the cells derived from monocytes, which are effective

12

in inducing self-tolerance, also lymphocytes, see Example 4, as well as optionally further cells derived from the mononuclear cell fraction, as for instance granulocytes. The amount of cells derived from monocytes within the STIC-population is

5   preferably 50 to 90 %, more preferably 60 to 70 %, referring to the total cell number.

With respect to the present invention the term "total cell number" refers to the amount of vital cells in the cell popu-

10   lation under consideration. This amount can be determined by the "trypan blue dye exclusion technique", since this dye allows to distinguish vital cells from non-vital cells by optical means.

15   The STIC may usually be used in a quantity of 10^4 - 10^6 cells per kilogram body weight, preferably 10^5 cells per kilogram body weight, to induce self-tolerance. STIC administration may be carried out repeatedly.

20   The STIC according to the invention have proved to be risk-free regarding the formation of malignoma, both in the animal test and in culture; this is a result which could not have been expected in any other way because of the nature of the original monocytic cell from which the cells according to the

25   invention are derived.

As in detail explained below, further sub-populations of cells having optimized self-tolerance inducing properties can be isolated from the fraction of cells present in STIC, which

30   are derived from monocytes.

Following in vitro cultivation and stimulation of the original cells (monocytes) with γ-interferon, STIC are formed, which comprise a sub-population of cells, see Example 3, which binds

the monoclonal antibody GM-7, which is expressed by the hybridoma cell line DSM ACC2542. The monoclonal antibody GM-7 is an antibody of the immunoglobulin isotype IgG$_{2a}$, the light chain of which exhibits the kappa-isotype. The characteristic

5 property of this antibody is its stringent capacity to bind to the monocytes modified by the culture conditions according to the invention since original monocytic cells are not recognised, i.e. binding of the antibody to the original cells does not take place, (see Example 3). In addition, it was demon-

10 strated with 20 volunteers that GM-7 does not bind to human cells in the peripheral blood, see Figure 5.

As described in PCT/EP03/075551, the antibody was prepared by immunising mice with TAIC (corresponding to STIC) derived from

15 human monocytes using methods known to the person skilled in the art (Davis, W.C. "Methods in Molecular Biology: Monoclonal Antibody Protocols", New York: Humana Press Inc. Totowa, 1995). A hybridoma cell line was then produced by fusion of a B cell generating the antibody and a myeloma cell from the

20 mouse. Methods used for the preparation of such cell lines are known in the state of the art (Davis, W.C. "Methods in Molecular Biology: Monoclonal Antibody Protocols", New York: Humana Press Inc. Totowa, 1995; Kohler, G., Milstein, C. "Continuous cultures of fused cells secreting antibody of predefined

25 specificity", Nature 256, 495-497 (1975)). The hybridoma cell line producing the antibody GM-7 was deposited according to the rules of the Budapest Convention at DSMZ (Deutsche Sammlung von Mikroorganismen und Zellkultur GmbH, Braunschweig, Germany) under the accession no. DSM ACC2542.

30
Figure 1 shows the binding capacity, determined by flow cytometry, of GM-7 to monocytic cells after *in vitro* modification according to the invention. It can be seen that the CD14-positive monocytes obtained directly from the mononuclear cell

14

fraction do not bind the antibody GM-7 (the cloud shaded grey
is congruent with the non-shaded antibody control). In con-
trast, following cultivation in the presence of M-CSF and
stimulation with γ-IFN, part of the monocytes express an anti-
5   gen which is recognised by the monoclonal antibody GM-7. The
monoclonal antibody GM-7 was characterised as isotype κ-IgG$_{2a}$.
The process according to the invention consequently leads to a
change in the phenotypic pattern of the antigen expression on
the cell membrane of the modified monocytes (Figure 1).

10

The monoclonal antibody GM-7 binds specifically to that cell
population which, among those cells produced by the process
according to the invention, induce the most effective self-
tolerance inducing cells (see Figure 5).

15

Therefore, a preferred embodiment of the invention relates to
such STIC, which are capable of binding the antibody GM-7.
These cells are subsequently designated as STIC$_{GM7}$.

20   The antibody GM-7 according to the invention therefore repre-
sents an extraordinarily effective and easy to handle agent
for selecting and purifying the cells inducing self-tolerance
(STIC). By means of the antibody, it is possible according to
the invention to generate a homogeneous and highly effective
25   STIC population.

According to a preferred embodiment of the invention, the
self-tolerance inducing cells formed in step c) of the above
described process of the invention, which express the antigen
30   binding to the antibody GM-7, may either be selected directly
from the culture medium after step c), or they may be selected
from the cell population obtained after separating the cells
from the culture medium according to step d) of the above-
mentioned process of the invention respectively, by binding to

15

the antibody GM-7 produced by the hybridoma cell line DSM
ACC2542.

To select the STIC according to the invention, the antibody is
5   contacted with the sample under conditions which permit bind-
ing of the antibody to the self-tolerance inducing cells pres-
ent in the sample. The reaction complexes resulting from the
binding reaction are subsequently separated from the sample.
For this purpose, the antibody can be immobilised on a carrier
10 material before contact with the sample; for example, it can
be bound to a matrix suitable for chromatographic purposes or
to so-called "magnetic beads". This procedure allows to select
and concentrate self-tolerance inducing cells from large vol-
umes of sample.
15

To obtain the self-tolerance inducing cells, the bond between
the antibody and the self-tolerance inducing cells is sepa-
rated after the isolation of the reaction complex from the
sample. This can be effected by methods known in the state of
20 the art such as e.g. by competitive displacement or by washing
with salt solutions. Corresponding methods are for instance
described by Utz U. et al. ("Analysis of the T-cell Receptor
repertoire of human T-cell leukemia virus type-1 (HTLV-1)
Tax-specific CD8+ Cytotoxic T Lymphocytes from patients with
25 HTLV-1 associated disease: Evidence for the oligoclonal ex-
pansion" J. of Virology Feb. 1996, 843-851).

Moreover, the monoclonal antibody GM-7 permits the qualitative
and quantitative detection of the self-tolerance inducing
30 cells of monocytic origin according to the invention in blood
and/or tissue samples of the patient *in vitro*. The formation
of reaction complexes in the sample which indicate the pres-
ence and, if applicable, the quantity of the self-tolerance
inducing cells is detected by known methods.

To detect the reaction complexes, it is possible in this case
to couple ("label") the antibody GM-7, for example, directly
with a detectable molecule which is e.g. covalently bound to
5   the antibody. Suitable detectable molecules are described in
large numbers in the field of molecular diagnostics and in-
clude, among others, fluorescent dyes such as fluorescein iso-
thiocyanate or tetramethyl rhodamine-5-isothiocyanate, lumi-
nescent dyes, radioactively labelled molecules and enzymes
10   such as peroxidases (compare Lottspeich, F., Zorbas, H. "Bio-
analytik", Spektrum Akademischer Verlag GmbH, Heidelberg-
Berlin, 1998).

The detection of the antibody takes place dependent of the
15   molecule selected for labelling of the former. In connection
with the present invention, the antibody GM-7 was coupled with
the fluorescent molecule fluorescein isothiocyanate (FITC) so
that the detection of the antibody could be carried out by
means of flow cytometry and/or fluorescence microscopy. Meth-
20   ods for labelling antibodies with FITC are known to the person
skilled in the art who operates in the field.

Alternatively, the reaction complex can also be detected in a
two-stage process using secondary antibodies. In this connec-
25   tion, the unlabelled antibody GM-7 can be detected in the re-
action complex with a further labelled antibody (compare Lott-
speich, F., Zorbas, H. "Bioanalytik", Spektrum Akademischer
Verlag GmbH, Heidelberg-Berlin, 1998). This two-stage method
of detection is considerably more sensitive than the direct
30   detection of binding of the antibody according to the inven-
tion since several labelled secondary antibodies can bind to
one GM-7 antibody (signal amplification).

17

The antibody GM-7 consequently allows the detection of STIC in the peripheral blood of the patient treated with STIC, for example in the form of "monitoring", during which the number of cells in the peripheral blood is determined at specific time
5   intervals.

As is obvious to the person skilled in the art, it is possible to prepare monoclonal antibodies against STIC from monocytes also of non-human vertebrates, in particular from monocytes of
10   primates and pigs modified according to the invention. In this respect, the immunisation of the corresponding host animals and the generation of the corresponding hybridoma cell line are carried out as described above for the STIC of human origin.
15

A particularly preferred embodiment of the invention relates to a sub-population of the STIC of the invention, which co-express the antigens CD3 and CD14 on their cell surface. These cells are subsequently indicated as $STIC_{CD3+/CD14+}$. As ex-
20   plained in more detail below, these cells have been shown to induce the formation of regulatory T-lymphocytes.

STIC which co-express the surface antigens CD3 and CD14 may either be directly selected from the self-tolerance inducing
25   cells formed in step c) of the above described process of the invention, or they may be selected from the cell population obtained after separating the cells from the culture medium according to step d) of the above-mentioned process of the invention, or they may alternatively be selected from the $STIC_{GM7}$
30   population.

Further, it has been shown by reference to the TAIC of PCT/EP03/07551 that the cells prepared according to the process described herein express the genes Foxp3, CTLA4 and Inte-

18

grin $\alpha_E\beta_7$ strongly (see Example 6, which corresponds to example 12 of PCT/EP03/07551). In contrast, these genes are not or only to a small extent expressed by the original monocytes. The upregulation of the expression of the genes Foxp3,

5   CTLA4 and Integrin $\alpha_E\beta_7$ is therefore a characteristic of STIC$_{CD3+/CD14+}$-cells.

As discussed in Example 6, the expression of the markers FoxP3, CTLA4 and Integrin $\alpha_E\beta_7$ was previously only described

10   for regulatory T-lymphocytes. T-lymphocytes, which co-express the surface antigens CD4 and CD25 are a sub-population of regulatory T-lymphocytes, which are also indicated as "suppressor cells". It is their function to suppress the immune response of the body. In particular, Foxp3 is seen as a spe-

15   cific transcription factor, which serves as a control gene for the development of regulatory T-cells, and which is specifically expressed by these cells. According to the invention, it is preferred that the STIC$_{CD3+/CD14+}$-cells express at least 1×10^{-9}, more preferably at least 5×10^{-9}, and in par-

20   ticularly preferred manner at least 1×10^{-8} µg Foxp3-RNA per µg total RNA.

CTLA4 is similarly viewed as a marker for the detection of the regulatory function of T-lymphocytes, in particular of

25   CD4/CD25 positive T-lymphocytes (see the literature cited in Example 6). According to the invention, the STIC$_{CD3+/CD14+}$-cells should preferably express at least 5×10^{-7}, more preferably at least 3×10^{-6} and in a particularly preferred manner at least 5×10^{-6} µg CTLA4-RNA per µg total RNA.

30

Integrin $\alpha_E\beta_7$, which recognizes epithelial Cadherin was recently described by Lehmann et al. in PNAS **99**, pages 13031-

13036 (2002) as a new marker for a sub-population of highly potent regulatory T-lymphocytes, which interact with the epithelial environment. The expression of the Integrin $\alpha_E\beta_7$-RNA should according to the invention amount in $STIC_{CD3+/CD14+}$-

5   cells to preferably at least 1×10^{-12}, more preferably to at least 1×10^{-11}, and in a particularly preferred manner to at least 1×10^{-10}, and most preferably to at least 1×10^{-9} µg per 1 µg total RNA.

10   As shown in the Table in Example 6, the direct co-culturing of the cells of the invention with lymphocytes leads to a significant increase in the number of regulatory T-lymphocytes, in particular of $CD4^+/CD25^+$ cells in the lympho-cyte population with strongly up-regulated expression of the

15   genes Foxp3, CTLA4 and Integrin $\alpha_E\beta_7$. The Example further dem-onstrates that this effect is not observed if the cells of the invention are indirectly co-cultured with lymphocytes.

These results indicate that stimulation of the formation

20   and/or propagation of regulatory T-lymphocytes by the cells of the invention is involved in the induction of self-tolerance by these cells.

Example 7 (corresponds to Example 13 of PCT/EP03/ß7551) con-

25   firms the hypothesis of an involvement of the cells of the invention in the induction of an immune response suppression by reference to the TAIC of PCT/EP03/07551 (see above). In this Example, lymphocytes from recipient animals were incu-bated with immune suppressive cells from the respective donor

30   animals *in vitro*. For the induction of tolerance, lymphocytes from the recipient pre-incubated with donor derived TAIC were injected to the animals instead of TAIC. Donor specific tolerance could be induced also in this manner, while ani-

20

mals, to which recipient lymphocytes not co-cultivated with donor derived TAIC were administered, did not develop tolerance.

5   The STIC of the invention can be used as such as a pharmaceutical preparation. The cells obtained from step d) of the method of the invention as described above can be used directly. About 10 - 50 % of the total cells of the populations so obtained is formed by lymphocytes and granulocytes, which
10   stem from the initial monocyte isolate (mononuclear cell fraction). These cells support the formation of the STIC of the invention derived from the monocytes in the culturing step (see Example 4); they do not interfere with the induction of self-tolerance if the STIC of the invention are used
15   as a pharmaceutical preparation.

However, according to further preferred embodiments of the invention, the sub-populations $STIC_{GM7}$ and/or $STIC_{CD3+/CD14+}$ may be isolated from the totality of the STIC population obtained
20   from process of the invention (see above) and may be used for self-tolerance induction.

In culture media (see Example 2), the STIC and/or the $STIC_{GM7}$ and/or $STIC_{CD3+/CD14+}$ may be kept for at least 48 hours without
25   their self-tolerance inducing effect becoming lost.

For use as pharmaceutical preparation, the STIC and/or the subpopulations $STIC_{GM-7}$ and/or $STIC_{CD3+/CD14+}$ suspended in e.g. human ABO compatible serum (universally suitable for use) can be
30   administered intravenously as short transfusion.

In this context pharmaceutical preparations may comprise the STIC of the invention in combination with conventional antiinflammatory agents and/or conventional immunosuppressants such

21

as steroids, in particular cortisone, methotrexate, cyclophos-
phamide, azathioprine, 5-aminosalicylic acid (5-ASA), TNF-
α antibodies, α-interferon and B cell antibodies, such as
e.g. Rituximab, for the treatment of organ specific or sys-
5   temic autoimmune diseases.

Further, the STIC of the invention may be used for the treat-
ment of allergies in combination with antihistaminics, theo-
phylline preparations, ß-mimetics, steroids, in particular
10   cortisone, and chromoglycine acid.

Detailed description of the invention

15

The starting cells for the process according to the invention
are autologous blood monocytes, i.e. monocytes from the blood
of the respective patient to whom the cells of the invention
are to be administered. Preferably, the autologous monocytes
20   are from human blood. The monocytes may be obtained by any
isolation process, in particular by leukapheresis or from the
mononuclear cell fraction from whole blood (buffy coat). Leu-
kapheresis is particularly preferred.

25   Leukapheresis is a general term for a multi-step procedure us-
ing a commercially available apheresis apparatus, wherein
whole blood from a human subject is withdrawn, separated into
fractions and the fractions, except for the mononuclear cell
fraction, are retransfused into the human subject. This proce-
30   dure may be carried out as outlined e.g. in further detail in
EP 0 591 194 B1.

Alternatively, the blood can first be separated, after the usual treatment with an anticoagulant, into plasma and into white and red blood cells using methods known in the art, preferably by centrifugation. After centrifugation, the plasma

5   will be present in the supernatant; below it, there is a layer which contains the white blood cells in their entirety. This layer is also referred to as buffy-coat. Below this is the phase containing the red blood cells (hematocrit).

10   In connection with the process according to the invention, the mononuclear cell fraction is first isolated and separated to obtain the monocytes e.g. by centrifuging according to known methods. According to a preferred process embodiment, the mononuclear cell fraction is applied onto a lymphocyte separa-

15   tion medium (Ficoll-Hypaque) and centrifuged (see Example 1). Example 1 describes the preferred embodiment of the invention, wherein the erythrocytes and dead cells which might still be contained in the mononuclear cell fraction are separated by centrifuging, and the white blood cells including

20   the monocytes are present as an isolate on the separation medium. Thereafter, the white phase may be carefully pipetted off, and, for enrichment of the monocytes within the isolate, is repeatedly centrifuged and washed. In the course of this process, the monocytes will assemble at the bottom of the

25   centrifuge vessel together with a part of the lymphocytes.

According to a particularly preferred embodiment of the method of the invention, the conditions for obtaining the monocyte containing isolate are controlled such that the iso-

30   late contains about 10 - 50 % lymphocytes next to the monocytes, by reference to the total number of cells. Preferably, the isolate contains about 50 - 90 %, in a particularly preferred manner 60 - 70 % monocytes and about 10 - 50 %, in a particularly preferred manner 20 - 50 % lymphocytes, each by

reference to the total cell count, wherein the difference will optionally be provided by granolocytes.

As shown in Example 4, the presence of lymphocytes in a mag-
5   nitude of 20 - 30 %, referred to the total cell count, during the culturing of the original monocytes with MCSF and γ-interferon will lead to the generation of a significantly higher amount of CD3/CD14-double positive STIC, as will be the case if only few lymphocytes (about 5 %) are present (see
10   Figure 3).

To prepare a sufficient quantity of STIC it is first necessary to allow propagation of the monocytes. For this purpose, known growth media suitable for monocytes can be used; however, the
15   medium must contain the growth factor M-CSF (macrophage-colony-stimulating-factor). M-CSF (also-called CSF-1) is produced by monocytes, fibroblasts, lymphocytes and endothelial cells. The concentration of M-CSF in the culture medium may preferably amount from 2 to 20 µg/l medium, more preferably 4
20   to 6 µg/l and in particularly preferred manner 5 µg/l.

Preferably, the growth medium does not contain the granulocyte macrophage colony stimulating factor (GM-CSF), because the yield of STIC is reduced in the presence of this factor.
25
Subsequently or simultaneously, the cells must be stimulated with γ-IFN, i.e. they must be cultured in the presence of γ-IFN. The stimulation of the monocytes with γ-IFN takes place after an initial propagation phase lasting 3 to 6 days in the
30   culture medium containing the growth factor. Preferably on day 4 after the beginning of cultivation in the presence of M-CSF, γ-IFN stimulation is started and this stimulation is extended over a period of preferably 24 to 72 hours, more preferably 48

24

hours under incubator conditions i.e. at 37°C and in a 5% CO_2 atmosphere.

The concentration of γ-IFN in the medium may be 0.1 to 20
5   ng/ml, preferably 1 to 10 ng/ml and particularly preferably 5 ng/ml.

The stimulation with γ-IFN may begin simultaneously with the propagation of the monocytes in the medium containing the
10   growth factor. However, stimulation after a 3 to 6 day long initial propagation phase, as indicated above, is preferred. The propagation of the cells and stimulation with γ-IFN should, overall, preferably not take more than 8 days. In any case, treatment with γ-IFN should be carried out such that af-
15   ter the propagation phase it lasts for at least 24 hours, at maximum 72 hours, preferably 48 hours. The period for propagation and stimulation of the cells should consequently last for a total of preferably 4 to 8 days.

20   According to a preferred embodiment of the invention, the propagation and stimulation with γ-interferon is carried out as indicated in Example 2 in such a way that the monocytes are first propagated in a culture medium containing the growth factor and that γ-IFN is added to the culture medium after 3
25   to 6 days in such an amount that a concentration of 0.1 to 20 ng/ml, preferably 1 to 10 ng/ml and particularly preferably 5 ng/ml is obtained in the medium.

Preferably, the process according to the invention is carried
30   out in culture vessels the surface of which has previously been coated with fetal calf serum (FCS) or preferably with human ABO compatible serum (see Example 2). Coating with FCS can take place by covering the surface of the culture vessels with

25

FCS before use and, following a period of interaction of a few hours, in particular 4 to 72 hours, preferably 12 to 48 hours and in particular 24 hours, removing the FCS not adhering to the surface in a suitable manner. The coating with human ABO

5   compatible serum is carried out in the same manner as described above.

During the culturing step the cells will settle at the bottom of the culturing vessel after about 24 hours. Due to their

10 adhesive properties the monocytes and the STIC, derived from the monocytes during the process, will then adhere to the bottom of the respective culture vessel. If, as described in Example 2, the culture medium is changed during cultivation, the supernatant is initially carefully removed, for instance

15 by pipetting off or decanting, and subsequently fresh culture medium is filled in. Preferably, however, the cells adhering to the bottom are not or only carefully washed, so that any lymphocytes present are not removed.

20 Removing the adhering cells can take place mechanically, e.g. by means of a fine cell scraper or spatula.

According to a preferred embodiment of the process according to the invention, however, the complete removal of the cell

25 takes place by treatment with a suitable enzyme, e.g. with trypsin (see Example 2). The trypsin solution (0.1 to 0.025 g/l, preferably 0.05 g/l) can be allowed to act onto the cells for 2 to 10 minutes at 35°C to 39°C, preferably at 37°C, in the presence of 5% CO_2.

30

The enzyme activity is then blocked in the usual manner and the now freely floating STIC can be obtained in the usual way by centrifuging. They are then available for immediate use,

26

optionally in suspension in a suitable medium, e.g. in PBS. However, they can also be kept for several days, in particular for approximately 2 to 3 days, in a nutrient medium (see Example 2), wherein this preservation medium should contain neither the growth factor nor γ-IFN. The cells can be kept in such a nutrient medium as STIC for at least 48 hours.

For storage over longer periods, the cells can be deep frozen. Protocols for deep freezing of living cells are known in the state of the art, compare Griffith M. et al., ("Epithelial Cell Culture, Cornea", in Methods of tissue engineering, Atala A. and Lanza R.P., Academic Press 2002, chapter 4, pages 131-140). A preferred suspension medium for deep freezing of the cells according to the invention is AB0 compatible serum or FCS both supplemented with DMSO.

According to one embodiment of the invention the cell suspension containing self-tolerance inducing cells obtained from steps c) or d) may be further purified with respect to those cells, which bind the antibody GM-7, so as to obtain a sub-population $STIC_{GM7}$. Methods for such purification are described above in detail.

According to a further preferred embodiment of the invention such cells are selected from the STIC population, which co-express the antigens CD3 and CD14 on their cell surfaces. Methods for selecting such cells are known in the art. Examples for such methods are the "Fluorescent-Activating Cell Sorting" (FACS), the "Immuno Magnetic Bead Sorting" and the "Magnetic Activated Cell Sorting" (MACS), or the so-called "Rosetting Method" [see Gmelig-Meyling F. et al. "Simplified procedure for the separation of human T- and non-T-cells", Vox Sang. 33, 5-8 (1977)].

27

The selection of the STIC sub-population $STIC_{CD3+/CD14+}$ can take place directly from the STIC population obtained from steps c) or d) of the above-described process of the invention, or from the $STIC_{GM7}$-sub-population. The latter way to proceed means

5   that a stepwise enrichment of $STIC_{CD3+/CD14+}$ will take place.

In a preferred embodiment of the invention the cells of the $STIC_{CD3+/CD14+}$ sub-population according to the invention are used per se for the production of a pharmaceutical composition for

10   the *in vivo* prevention and/or treatment of autoimmune diseases.

Examples of such autoimmune diseases are:

15   • Rheumatic diseases with autoimmune features, in particular rheumatoid arthritis, SLE, Sjögren's disease, scleroderma, dermatomyositis, polymyositis, Reiter's syndrome;

     • Diabetes mellitus;

20

     • Autoimmune diseases of the blood and blood vessels, in particular autoimmune hemolytic anemia (AIHA), autoimmune thrombocytopenic purpura (ITP), anti-phospholipid antibody syndrome, vasculitis (Polyarteritis nodosa group, Wegener's

25   granulomatosis, hypersensitivity vasculitis, giant cell arteritis), systemic lupus erythematosus, mixed essential cyroglobulinemia;

     • Autoimmune diseases of the liver, in particular autoimmune

30   hepatitis, primary biliary cirrhosis and primary sclerosing cholangitis;

28

- Autoimmune diseases of the thyroid, in particular Hashi-
  moto's disease, Graves' disease;

- Autoimmune diseases of the central nervous system, in par-
5   ticular multiple sclerosis, myasthenia gravis; and

- Bullous Skin Diseases, in particular pemphigus vulgaris,
  pemphigus vegetans, pemphigus foliaceus, Senear-Usher syn-
  drome and Brazilian pemphigus.
10

The usefulness of STIC for inducing self-tolerance is shown
for mice in two model systems of artificially induced colitis
resembling an autoimmune disease (see Examples 8 and 9).

15   These models are the dextran sulphate sodium (DSS)-induced
chronic colitis (Example 8) and the $CD62L^+/CD4^+$ SCID transfer
model of chronic experimental colitis in mice (Example 9). In
both models mice develop a chronic colitis with symptoms re-
sembling the human colitis ulcerosa.
20

In both model systems administration of STIC shortly after the
disease onset leads to the suppression of the typical symptoms
of the colitis compared to untreated animals or animals
treated with "control cells" that do not contain STIC (see Ex-
25   amples 8 and 9).

As discussed above, excessive immune reactions are also in-
volved in the development of allergies. It has been shown by
Bach et al. (loc. cit.), that $CD4^+$ cells, which comprise
30   $CD4^+/CD25^+$ cells as a subpopulation, can mitigate the progres-
sion of experimental allergic encephalomyelitis (EAE). Since,
as shown herein, the administration of STIC results in the in-

29

duction of an increase of the $CD4^+/CD25^+$ T cell population, the cells are also useful for the treatment of allergies.

So, according to a further preferred embodiment of the inven-
5   tion, STIC containing pharmaceuticals are used for the preven-
tion and/or treatment of allergies.

Pharmaceutical preparations may contain vital STIC according to the invention, which are obtained from step d) of the proc-
10   ess of the invention, suspended in a pharmaceutically accept-
able carrier preferably in a quantity of about 1×10^5 to 1×10^7 cells/ml and more preferably of about 1×10^6 cells/ml of the preparation.

15   In a further preferred embodiment of the invention the cells of the $STIC_{GM7}$ sub-population according to the invention are used per se for the production of a pharmaceutical composition for the *in vivo* prevention and/or treatment of diseases asso-
ciated with disturbed self-tolerance.
20
In one embodiment of the invention such pharmaceutical prepa-
ration may contain vital $STIC_{GM7}$ cells according to the inven-
tion, which bind to the antibody GM-7, suspended in a pharma-
cologically acceptable liquid carrier, preferably in a quan-
25   tity of about 1×10^6 to 1×10^8 cells/ml and more preferably of about 1×10^6 cells/ml of the preparation.

In the most preferred embodiment of the invention such pharma-
ceutical preparation may contain vital $STIC_{CD3+/CD14+}$ cells ac-
30   cording to the invention, which co-express the antigens CD3 and CD14, in a quantity of preferably about 5×10^5 to 5×10^7 cells/ml and more preferably of about 5×10^6 cells/ml of the preparation.

The above described pharmaceutical preparations may contain
the cells according to the invention suspended in a physio-
logically well-tolerated medium. Suitable media are for exam-
5   ple Ringer solution, physiological saline or 5 to 20 % human
albumin solution and the like.

The pharmaceutical compositions containing STIC according to
the invention may be administered via a variety of routes of
10   administration depending on the body site(s) affected by the
respective disease. In preferred embodiments of the invention
said pharmaceutical compositions can be administered intrave-
nously, intraportally, subcutaneously, intradermally, intra-
peritoneally or intrathecally. The pharmaceutical compositions
15   can further be administered directly into a specific organ,
such as the liver or muscle, per inhalation or into body cavi-
ties.

The pharmaceutical preparations containing STIC as active in-
20   gredients can also be used for the prevention of autoimmune
diseases in those cases where the gene responsible for the de-
velopment of the disease is known. If an individual is diag-
nosed as a carrier of a gene associated with one or more auto-
immune diseases, the outbreak of the disease can be prevented
25   by administering STIC derived from autologous monocytes in an
early stage of life. In a preferred embodiment of the inven-
tion the autologous STIC are cocultured with autologous lym-
phocytes and with the peptide expressed by the respective
gene. This will lead to the development of autologous regula-
30   tory T-lymphocytes specific for the respective gene product.
These regulatory T-lymphocytes can then be re-administered to
the respective individual as described below in Example 7
(corresponds to Example 13 of PCT/EP03/07551).

In a further embodiment of the invention, STIC can be used for prevention in those cases where the autoimmune disease occurs in intervals, as for instance in rheumatoid arthritis. If the pharmaceutical preparation containing STIC is administered af-
5 ter the first or a subsequent break out of the disease, further break outs can be prevented.

Cell preparations according to the invention may contain vital STIC, which are obtained from step d) of the process of the
10 invention. Alternatively, the preparations may contain cells belonging to the sub-populations of $STIC_{GM7}$ cells, which bind to the antibody GM-7, or of $STIC_{CD3+/CD14+}$ cells, which co-express the antigens CD3 and CD14 on their cell surface. The prepara- tions may contain the respective cells in a quantity of pref-
15 erably at least 1×10^5, more preferably at least 5×10^5 and most preferably at least 1×10^6 cells per ml suspended in a liquid carrier medium. The medium may be a cell culture or transport medium well-tolerated by cells, such as 5 to 20% hu- man albumin solution. Alternatively, the cells within the
20 preparation may be deep-frozen and contained in a suitable storage medium, such as e.g. RPMI with 50% human albumin solu- tion and 10% DMSO.

Finally, the invention also relates to a method wherein the
25 self-tolerance inducing cells of the invention (STIC, $STIC_{GM7}$ or $STIC_{CD3+/CD14+}$) are used for generating or expanding autologous regulatory T-lymphocytes *in vitro*. As shown in Example 6 (cor- responding to Example 12 of PCT/EP03/07551), the direct *in vi- tro* cocultivation of TAIC, corresponding to STIC with lympho-
30 cytes leads to a significant proliferation of regulatory T- lymphocytes, in particular of $CD4^+/CD25^+$ lymphocytes. It is therefore possible to generate and/or expand autologous regu- latory T-lymphocytes, in particular $CD4^+/CD25^+$ lymphocytes, by

directly coculturing STIC derived from monocytes of an individual with autologous lymphocytes.

Direct *in vitro* culturing means according to the invention
5 that STIC and lymphocytes are cocultured in direct physical contact within the same medium, as l.c. exemplified in Example 6.

In this method the medium preferably contains the respective
10 cells i.e. STIC and lymphocytes in about equal cell numbers and each in a quantity of preferably at least 1×10^5, more preferably at least 5×10^5 and most preferably at least 1×10^6 cells per ml suspended in a liquid carrier medium; the medium may be a cell culture or transport medium well-tolerated
15 by cells, such as 5 to 20% human albumin solution. The co-cultivation preferably should take place under physiological conditions at about 37°C, e.g. in an incubator, for preferably about 3 to 5, more preferably 4 days.

20 It was shown in Example 7 (corresponding to Example 13 of PCT/EP03/07551), that transplant acceptance can not only be induced by administering TAIC generated from donor monocytes to the recipient, but also by readministering recipient lymphocytes to the recipient, which have previously been directly
25 cocultured *in vitro* with TAIC prepared from donor monocytes as described above. Similarly, self-tolerance can be induced by readministering autologous lymphocytes to the patient, which have previously been directly co-cultured with STIC prepared from the patient's own monocytes.
30

According to a further embodiment of the invention regulatory T-lymphocytes can therefore be prepared *in vitro* from lymphocytes originating from the individual to be treated, by direct

coculturing of lymphocytes from this individual with STIC originating from monocytes of this individual. Readministering the cocultivated lymphocytes to the recipient will lead to induction of self-tolerance, as shown in Example 7.

5

The regulatory T-lymphocytes so prepared may be isolated by FACS as described herein (see above) and may be used in a pharmaceutical preparation for preventing and/or treating of diseases associated with disturbed self-tolerance wherein the

10 cells are suspended in a pharmacologically acceptable carrier as described above.

The invention is illustrated in further detail by way of examples.

15

If not defined within the examples, the composition of the media and substances used are as follows:

1. Penicillin/streptomycin solution:

20   10,000 units of penicillin as sodium salt of penicillin G and 1000 µg streptomycin as streptomycin sulphate per ml physiological sodium chloride solution (NaCl 0,85 %) (Gibco Catalogue No. 15140122).

25 **2. Trypsin-EDTA**
        0.5 g trypsin and 0.2 g EDTA (4 Na)/l

3. RPMI 1640 (1x, liquid (11875))
    contains L-Glutamine

30

        RPMI (Roswell Park Memorial Institute) Media 1640 are enriched formulations, which can be used extensively for mammalian cells.

Example 1
Separation of Monocytes from whole Blood

5   Whole blood was obtained from human patients by two different methods:

a) Leukapheresis: Leukapheresis was carried out using a COBE®
Spectra™ apheresis system (Gambro BCT, Lakewood, CO, USA) in
10   the mononuclear mode (MNZ) according to the manufacturer's instructions (COBE Spectra Version 4.7/5.1/6.0/7.0).

b) Conventional separation of blood components: 450 ml whole blood was mixed in a triple chamber bag set with 63 ml of a
15   stabiliser solution which contained, per litre H_2O, 3.27 g of citric acid, 26.3 of g trisodium citrate, 25.5 g of dextrose and 22.22 g of sodium dihydroxy phosphate to avoid coagulation of the blood and to feed the cells. The pH of the solution was 5.6-5.8.
20

To separate the components of the blood, "sharp centrifuging" of this mixture was subsequently carried out at 4000 rpm for 7 minutes at 20°C. This resulted in the layering of the corpuscular and non-corpuscular components within three layers. By us-
25   ing the bag set in a compression machine provided for this purpose, the erythrocytes were then pressed into the lower bag, the plasma was pressed into the upper bag and the so-called buffy-coat remained in the middle bag and contained a volume of approximately 50 ml.
30

From both methods, the quantity of 50 ml of freshly obtained mononuclear cell fraction was then divided into 2 portions of 25 ml each and layered onto 25 ml of Ficoll-Hypaque separation

37

medium respectively which had been introduced previously into
two 50 ml Falcon tubes.

This preparation was centrifuged for 30 minutes at 2500 rpm
5   without braking. Thereafter, any erythrocytes and dead cells
that might still be present in the mononuclear cell fraction
were below the Ficoll phase, whereas the white blood cells,
including the monocytes, were separated off on the Ficoll as
white interphase.
10

Subsequently, the white interphase including the monocytes was
carefully removed by pipetting and mixed with 10 ml of phos-
phate-buffered saline (PBS).

15   This preparation was then centrifuged three times for 10 min-
utes at 1800 rpm with braking, the supernatant being removed
by pipetting after each centrifuging process and fresh PBS be-
ing introduced.

20   The cell pellets assembled at the bottom of the centrifuging
vessel (Falcon tubes) contained the mononuclear cell fraction,
i.e. the monocytes.

c) The monocytes required for the mouse experiments 8 and 9
25   (performed with genetically identical mice) were obtained from
spleens of syngeneic donor mice. The spleens were passed
through a small meshed sieve under slight pressure and the
thus separated cells were resuspended in PBS. The suspended
spleen cells were layered onto a 25 ml Ficoll-Hypaque separa-
30   tion medium which had been introduced previously into 50 ml
Falcon tubes. The procedure was then continued in the same way
as described above.

Example 2

Propagation and Modification of the Monocytes

5 The cultivation and propagation of the monocytes was carried
out in nutrient medium with the following composition:

RPMI 1640 medium	440 ml
Fetal calf serum (FCS), alternatively, AB0 compatible serum	50 ml
Penicillin / Streptomycin Solution	5 ml
Total volume	500 ml

The nutrient medium contained 2,5 µg / 500 ml M-CSF.

10

The monocytes isolated in Example 1 were suspended in a total
quantity of 10^6 cells in 10 ml of the nutrient medium and
transferred onto a Petri dish (100 mm in diameter). The Petri
dish had previously been filled with pure inactivated FCS and

15 the FCS had been poured off after 24 hours in order to obtain,
in this way, a dish coated with FCS.

The Petri dish was covered with the appropriate cover and kept
for 3 days in an incubator at 37°C. The cells settled at the

20 bottom of the Petri dish after 24 hours. On day two, the su-
pernatant was pipetted off and the Petri dish again filled
with 10 ml of fresh nutrient medium.

On day 4, 50 ng γ-interferon in 10 ml nutrient medium were

25 added and the dish was again closed and kept for a further 48
hours in the incubator at 37°C.

Subsequently, 10 ml of trypsin solution each diluted 1:10 with
PBS were pipetted into the Petri dish. The closed Petri dish
was kept for 10 minutes in the incubator at 37°C.

5

Thereafter, the separation of the cells adhering to the bottom
of the Petri dish was carried out with a cell scraper in such
a way that the major part (>90%) of the cells floated in the
supernatant.

10

The total supernatant (10 ml of trypsin solution + 10 ml of
medium) was pipetted off, combined in a 50 ml Falcon tube and
centrifuged for 10 minutes at 1800 rpm. The supernatant was
then discarded and fresh nutrient medium (see above) was added

15 to the precipitate (the remaining cell pellet), 1 ml of nutri-
ent being added per 10^6 cells. The determination of the cell
count for the determination of the exact dosage took place ac-
cording to known methods, compare Hay R.J., "Cell Quantifica-
tion and Characterisation", in Methods of Tissue Engineering,

20 Academic Press 2002, Chapter 4, p. 55-84.

This cell suspension was centrifuged (1800 rpm, 10 minutes,
see above) and the cell pellet were incorporated either into
PBS or for application in man into NaCl (physiol.). Subse-

25 quently, the intravenous administration can take place di-
rectly or within 48 hours.

Alternatively, after centrifuging and discarding the super-
natant containing trypsin, FCS/DMSO was added as freezing me-

30 dium to the cells and these were deep frozen in a volume of 10
ml.

The freezing medium contained 95% FCS and 5% DMSO. In each case, approximately 10^6 cells were incorporated into 1 ml of the medium and cooled in the following steps:

5   30 minutes on ice;

         2 hours at -20°C in the pre-cooled Styropor box;

         24 hours at -80°C in Styropor;

         Storage in small tubes in liquid nitrogen (N_2) at -180°C.

10   Figure 1 shows the phenotypic changes in the antigen expression, determined by flow cytometry, on the monocytes used after cultivation and γ-IFN stimulation of the original monocytic cells. The cultivation and γ-IFN stimulation of the original monocytic cells leads to significantly increased
15   binding of GM-7 after modification (right hand graph in Fig. 1) compared to cells before modification (left hand graph in Fig. 1).

20   Examples 3 to 7 below are taken from PCT/EP03/07551. They characterise the transplant-acceptance inducing cells (TAIC) disclosed therein. Due to the similarity of the TAIC of PCT/EP03/07551 and the self-tolerance inducing cells (STIC) of the present invention (see above) the results reported in
25   these examples also apply to the STIC.

More precisely, the results of Examples 3 to 7 below show

■   that a cell population with optimised suppressor function
30   can be isolated from the TAIC population obtained after cultivation of original monocytes with M-CSF and γ-IFN-stimulation through the availability of the monoclonal antibody GM-7 (Example 3);

41

- that lymphocytes present in the monocyte fraction have a great influence on the generation of CD14$^+$/CD3$^+$-cells effective as TAIC (Example 4);

- that the IDO-inhibitor 1-methyltryptophane has no influence
5   on the suppressor function of the TAIC (Example 5);

- that direct *in vitro* co-culture of TAIC of donor A together with lymphocytes of a donor B. induces the formation of regulatory T-cells, i.e. CD4$^+$/CD25$^+$-lymphocytes (Example 6); and

10 - that the physical cell to cell interaction between donor-TAIC and recipient-lymphocytes *in vivo* induces the generation of regulatory T-cells capable of preventing organ rejection (Example 7).

15

Example 3
Binding of the Antibody GM-7 to TAIC

20   The monoclonal antibody GM-7 was generated by immunising mice with human TAIC which had been prepared as described in PCT/EP03/07551. The hybridoma cells producing the antibody were deposited at the "Deutsche Sammlung für Mikroorganismen" under the accession no. DSM ACC2542. The results reported be-
25   low demonstrate that the antibody binds specifically to an antigen which is expressed only on CD14$^+$ cells which had been subjected to the 6 day *ex situ* modification with M-CSF and 2 day γ-IFN stimulation according to the invention.

30   Figure 1 shows the binding capacity, determined by flow cytometry, of GM-7 to monocytic cells after *in vitro* modification, i.e. after transformation into TAIC. It can be seen that the CD14-positive monocytes obtained directly from buffy-coat

42

do not bind the antibody GM-7 (left-hand picture; the grey
shaded cloud corresponds to the antibody control). In con-
trast, part of the monocytes express an antigen after cultiva-
tion in M-CSF and stimulation with γ-IFN, which antigen is
5   recognised by the monoclonal antibody GM-7. After cultivation
as described in Example 2, about 80% of the transformed mono-
cytes are able to bind the monoclonal antibody GM-7 (right-
hand picture).

10   In a further experiment, the suppressor activity of the
CD14$^+$/GM-7$^+$ cells was compared with that of CD14$^+$/GM-7$^-$ cells
in a mixed lymphocyte culture (MLC). The MLC was carried out
as described by Kurnick, J.T. "Cellular Assays" in: Diagnostic
Immunopathology, [Colvin R.B., Bhan A.K., McCluskey, R.U.
15   (ed.), Raven Press, New York, pages 751-771 (1994)].

In this example, the TAIC stem from an individual B. As shown
in Figure 2, a significant difference exist between the sup-
pressor activity of the GM-7 positive and GM-7 negative TAIC.
20   Only the GM-7 positive fraction the TAIC population obtained
after 6 days treatment with M-CSF and 2 days stimulation with
γ-IFN exhibits a significant inhibition effect on the T-cell
proliferation activity of responder cells of the individual A
after stimulation with cells of B.

25

Example 4
Influence of Lymphocytes on the Formation of CD3$^+$/CD14$^+$-Cells
30   **during Monocyte Cultivation**

The influence of lymphocytes present in the monocyte fraction
on the generation of CD14$^+$/CD3$^+$-cells effective as TAIC was
determined by comparison of two different set ups.

For the first set up (subsequently indicated as "Mo") the
monocyte fraction was initially taken from the interphase of
the buffy-coat as described in Example 1. As described in Ex-
5   ample 2, the cells were subsequently transferred to the culti-
vation step with M-CSF. Within one hour after the starting
point of the cultivation, the monocytes adhering to the bottom
of the tissue culture flask were washed five times with 10 ml
PBS each, and the amount of the lymphocytes present in the
10   culture was thereby decreased to < 5 % (4.8 ± 2.4 %), while the
amount of enriched monocytes ($CD14^+$) so obtained was above 90 %
(92 ± 5.6 %). Additional cell components within the set up were
B-lymphocytes and granulocytes.

15   The cells in the second set up (subsequently indicated as
"Mo+Ly") were also taken from the interphase of the buffy-coat
as monocyte fraction as described in Example 1. However, dif-
ferent from set up "Mo" the cells adhering to the bottom of
the tissue culture flask were only washed once after 24 hours
20   starting from the beginning of the cultivation phase, as de-
scribed in Example 2. As a result, a cell population was ob-
tained, which was composed of 45 ± 5.3 % $CD14^+$-monocytes and
23.5 ± 8.9 % $CD2^+$-lymphocytes. As in set up "Mo" lymphocytes
and granulocytes were also present in this set up.
25
The determination of the amounts of the respective cell types
in the total cell population per set up was carried out
through flow cytometry of three experimental set ups each (see
Figure 3). The results are reported as mean values including
30   the standard deviation.

$CD14^+/CD3^+$-cells can neither be determined in the set up "Mo"
nor in the set up "Mo+Ly" at the beginning of the culture (d 0

= day 0). After a cultivation period of five days, the experiment was terminated and the cells were characterised by FACS-analysis after detaching the cells from the bottom of the tissue culture flask as described in Example 2. It was found that

5   the relative amount of CD14$^+$-cells decreases in these set ups, from 92 % to 42 % in set up "Mo" and from 45 % to 28 % in set up "Mo+Ly". Seemingly, the lymphocytes proliferate quicker than the monocytes; the relative amount of lymphocytes increased in set up "Mo" from 4.8 % to 69.8 % and in set up

10   "Mo+Ly" from 23.5 % to 50.6 %. During the cultivation, CD14$^+$/CD3$^+$-cells effective as TAIC are formed in both cultures. It is important in this context that a significantly higher increase in CD14$^+$/CD3$^+$-cells is observed in the set up "Mo+Ly" with an amount of 32.0 ± 5.3 % as opposed to set up "Mo" with

15   only 7.2 ± 3.2 %.

These results demonstrate that the purification of the cells for enrichment of monocytes to a relative amount of more than 90 % at the beginning of the cultivation has a negative in-

20   fluence on the generation of the immuno suppressive CD14$^+$/CD3$^+$-cells in the TAIC population, while the method described in Examples 1 and 2 leads to a significantly higher yield of CD14$^+$/CD3$^+$-cells.

25

Example 5

Determination of the Influence of the IDO Inhibitor 1-methyl-tryptophane on the Immunosuppressing Activity of the TAIC

30

In order to clarify, whether the inhibitor of the enzyme indolamine-2,3-dioxygenase (IDO) 1-methyltryptophane (1-MT) influences the suppressor function of the TAIC generated in the

"Mo" and "Mo+Ly" set ups (see Example 4), a variety of mixed lymphocyte cultures (MLC) with PHA (phytohaemagglutinine) stimulated T-cells in the presence and in the absence of 1-MT were established.

5

In these mixed lymphocyte cultures 50.000 lymphocytes with 2 µg PHA were transferred into the wells of a 96-well-plate, followed by a proliferation period over 144 hours (indicated as "PhaLy"). Lymphocytes only cultivated in medium without

10 addition of PHA were run as a further control (indicated as "Ly").

In order to determine the proliferation of PHA-stimulated lymphocytes in the different co-cultures, the following 4 set

15 ups were run and examined:

| PhaLy + "Mo+Ly" | PHA-stimulated lymphocytes and TAIC [10^5 cells from the set up "Mo+Ly" according to Example 4]. |

20

| PhaLy+"Mo+Ly"+1-MT | PHA-stimulated lymphocytes and TAIC in the presence of 2 µmol 1-MT [10^5 cells from the set up "Mo+Ly" according to Example 4]. |

25

| PhaLy + "Mo" | PHA-stimulated lymphocytes and TAIC [10^5 cells from the set up "Mo" according to Example 4]. |

30 | PhaLy+"Mo"+1-MT | PHA-stimulated lymphocytes and TAIC in the presence of 2 µmol 1-MT [10^5 cells from the set up "Mo" according to Example 4]. |

After 144 hours cultivation, all controls or co-cultures were further cultivated for 24 hours in the presence of $^3[H]$-thymidine ("pulsed") and thereafter the amount of radioac-
5   tively labeled thymidine incorporated was determined as counts per minute (cpm), see Figure 4. In this arrangement, the amount of the radio activity determined is a measure for the amount of labeled thymidine incorporated into the DNA, and therefore a measure for the proliferation rate of the
10 lymphocytes. The values reported in Figure 4 correspond to mean values from triple determinations of 3 experiments each with indication of the standard deviation.

The results demonstrated that lymphocytes not stimulated with
15 PHA ("Ly") do not significantly proliferate, the mean radio-activity observed being 367 cpm (see Figure 4). In contrast, the stimulation with 2 µg PHA leads to a significant increase in the proliferation rate of the lymphocytes ("PhaLy"), the highest incorporation being measured at a mean value of 18459
20 cpm in these samples.

The addition of TAIC to the lymphocyte cultures clearly de-creased the proliferation rate strongly if cells from the set up "Mo+Ly" from Example 4 were added (PhaLy + "Mo+Ly", deter-
25 mined value 1498 cpm), and less strongly when cells from the set up "Mo" from Example 4 were added (PhaLy + "Mo", measured value 3369 cpm).

The results obtained after addition of 2 µmol 1-methyl-
30 tryptophane (1-MT) to the set ups containing "Mo+Ly" and "Mo" with stimulated lymphocytes demonstrated that 1-methyl-tryptophane (1-MT) increases the suppressor function of the TAIC synergistically, whereby the decrease was stronger with

the TAIC from the set up "Mo+Ly" (measured value 267cpm) than
with the TAIC from the set up "Mo" (measured value 390 cpm).

5

Example 6

In vitro co-cultivation of human TAIC with allogeneic lymphocytes for generating regulatory T-cells

10 To examine whether TAIC induce the formation of regulatory T-
cells, i.e. $CD4^+/CD25^+$-lymphocytes, in the recipient, several
different *in vitro* cultures of TAIC with lymphocytes were run
and the formation of regulatory T-cells resulting therefrom
was analyzed.

15

For this purpose, TAIC of donor A were directly or indirectly
co-cultivated *in vitro* together with lymphocytes of a donor
B. In the direct co-culture, the direct cell-to-cell-contact
between the TAIC (of donor A) and the lymphocytes (of donor

20 B) was made possible, while in the indirect co-culture a mem-
brane ("cell culture insert", 0.4 μm pore size, Falcon, order
no. 353090) allowed exchange of the medium, but inhibited the
physical contact of the two cell populations. The direct or
indirect co-culture is carried out for preferably 3 to 5 days,

25 more preferably for 4 days under incubator conditions i.e. at
37°C and in a 5% CO_2 atmosphere.

After culturing, the respective numbers of regulatory T-cells
($CD4^+/CD25^+$) were determined in both set ups as well as in the

30 controls, wherein TAIC or lymphocytes respectively were cul-
tivated alone. Further, the number of $CD3^+/CD14^+$-cells, which
represent the component of the TAIC cell population having
the most significant suppressor function in the mixed lympho-

48

cyte culture, was determined in the control set up, wherein
the TAIC were cultured alone.

In all set ups, the surface antigens of the cells were deter-
5   mined per FACS analysis and the amount of the respective cell
populations in the total amount of the cells was analysed.

Further, the relative expression of three new master genes
specifically expressed by regulatory T-cells (Foxp3, CTLA-4
10 and Integrin $\alpha_E\beta_7$) was determined by PCR in the respective
cell population (see Table). Foxp3 is a specific transcrip-
tion factor, which is viewed as a control gene for the devel-
opment of regulatory T-cells, and which is specifically ex-
pressed by these cells [see Hori, S. et al., "Control of
15 Regulatory T-cell Development by the Transcription Factor
Foxp3", Science 299, 1057 – 1061 (2003)].

CTLA-4 is a further factor, which is used as a marker for the
determination of the regulatory function of $CD4^+/CD25^+$-T-cells
20 (see Khattri, R. et al., "An essential role for Scurfin in
$CD4^+/CD25^+$ T regulatory cells", Nature Immunology, online pub-
lication, doi:10.1038/ni909 (2003); Shimizu, J. et al.
"Stimulation of $CD25^+/CD4^+$ regulatory T cells through GITR
breaks immunological self-tolerance", Nature Immunology, on-
25 line publication, doi:10.1038/ni759 (2003); Cobbold, S.P. et
al. "Regulatory T cells in the induction and maintenance of
peripheral transplantation tolerance", Transpl. Int. 16(2),
66-75 (2003)].

30 Integrin $\alpha_E\beta_7$ is an integrin, which binds to epithelial Cath-
erine and which may be used as a marker for the most potent
sub-population of regulatory $CD25^+$-T-cells [see Lehmann, J.
et al. "Expression of the integrin $\alpha_E\beta_7$ identifies unique sub-

49

sets of CD25$^+$ as well as CD25$^-$ regulatory T cells" PNAS
99(20), 13031-13036 (2002)].

The determination of Foxp3-, CTLA-4- and integrin $\alpha_E\beta_7$-
5   expession was carried out by means of quantitative PCR using
GAPDH and β-actin, two "housekeeping genes", as controls; the
values determined were, on the one hand, placed in relation-
ship to each other, the value obtained for the CD14$^+$/CD3$^-$
cells being set at 1; on the other hand the absolute RNA
10   amounts were indicated in µg per µg total RNA, in order to
correlate the measured suppression effected by the TAIC *in
vitro* and the formation of the CD4$^+$/CD25$^+$ double positive
cells with the expression rate of the respective genes. Stan-
dard methods were used for the quantitative PCR, which are
15   known to the skilled person (see Lottspeich, F., Zorbas, H.
"Bioanalytik", Spektrum Akademischer Verlag GmbH, Heidelberg-
Berlin, 1998).

The Table shows that within the population of lymphocytes ob-
20   tained from the direct co-culture, the percentage of double
positive cells CD4$^+$/CD25$^+$ increases manifold to a value of 8.7
% in comparison to the amount of CD4$^+$/CD25$^+$ lymphocytes ob-
tained from the indirect co-culture or control, which is
nearly identical with 2.38 % and 2.65 %, respectively.
25

The sub-population of CD4$^+$/CD25$^+$ cells expresses the highest
relative amounts of mRNA from all tested mastergenes as com-
pared to the expression in CD4$^+$/CD25$^-$ cells (see Table). While
the expression of Foxp3 is increased by about a factor 10 (37
30   versus 3.75), CTLA-4 expression reaches an even higher maxi-
mum expression (4699 versus 0.376). The increase of expres-
sion of the third mastergene integrin $\alpha_E\beta_7$ in the CD4$^+$/CD25$^+$

cells during co-culturing is nearly as high as for CTLA-4 since the absolute amount of integrin $\alpha_E\beta_7$ mRNA is raised to

	Control				direct co-culture		indirect co-culture	
	TAIC		lymphocytes		lymphocytes		lymphocytes	
	CD14+/ CD3+	CD14+/ CD3-	CD4+/ CD25+	CD4+/ CD25-	CD4+/ CD25+	CD4+/ CD25-	CD4+/ CD25+	CD4+/ CD25-
FACS [% positive cells]	41	20	2.65	30,8	8.7	49	2.38	27.6
relative Foxp3-expression [PCR]	50	1	15	1,5	37	3.76	10	1.5
absolute RNA-amount Foxp3	1.6×10^{-8}	3.2×10^{-10}	4.8×10^{-9}	8×10^{-10}	1.2×10^{-8}	1.2×10^{-9}	3.2×10^{-9}	4.8×10^{-10}
relative CTLA4-expression [PCR]	12500	1	0.375	0.1	4699	0.376		
absolute RNA-amount CTLA4	$6,5 \times 10^{-6}$	5.2×10^{-10}	1.9×10^{-10}	5.2×10^{-10}	2.4×10^{-6}	1.9×10^{-10}		
absolute RNA-amount Integrin $\alpha_E\beta_7$	3.4×10^{-9}	not detect-able	1.4×10^{-9}	3.4×10^{-12}				

5 **Table:** Determination of the amounts of specific cell popula-
          tions in the total amount of cells after direct and
          indirect co-culture by reference to their surface
          markers CD3, CD4, CD14, CD25, and determination of
          the relative expression and the absolute amounts of
10   RNA of three genes (Foxp3, CTLA-4 and integrin $\alpha_E\beta_7$)
          in these cell populations.

1.4 × 10^{-9} in CD4$^+$/CD25$^+$ cells as compared to 3.4 × 10^{-12} µg mRNA/µg total RNA in CD4$^+$/CD25$^-$ cells.

5   After indirect co-culture, the relative amount of Foxp3-mRNA in the CD4$^+$/CD25$^+$ sub-population amounts to only 10 and is even lower as the relative amount expressed by the lymphocytes of the control, which expresses a relative amount of Foxp3-mRNA of 15.

10

The relative amount of CTLA-4-mRNA expressed by the lymphocytes of the control is as low as 0.375 in the CD4$^+$/CD25$^+$-population and 0.1 in the CD4$^+$/CD25$^-$population.

15   The expression of CTLA-4 in the CD14$^+$/CD3$^+$ sub-population of the TAIC cells was similar to the expression of Foxp3 and was also significantly higher than in all other cell populations.

In this regard, it is noteworthy that the CTLA-4 expression
20   (relative value of 12.500) was manifold stronger in the CD14$^+$/CD3$^+$-sub-population than the Foxp3-expression, which exhibited a relative value of 50.

No expression of the integrin $\alpha_E\beta_7$ was detectable in the
25   CD14$^+$/CD3$^-$ sub-population of the TAIC, while similar to the behavior of the expression of the other two analyzed genes, the expression of the integrin in the CD14$^+$/CD3$^+$-sub-population of the TAIC, measured as absolute value in µg RNA per µg total RNA, reached the highest value (3.4 × 10^9 µg / µg
30   total RNA).

The significantly increased expression of the three lymphocyte markers Foxp3, CTLA-4 and integrin $\alpha_E\beta_7$ on the TAIC de-

rived from monocytes as compared to normal lymphocytes is to-
tally unexpected and has to date never been observed on mono-
cytes or on cells derived from monocytes.

5   In conclusion, the results of this Example as shown above
demonstrate the following: If one starts from the assumption
that the level of Foxp3-, CTLA-4-, and integrin $\alpha_E\beta_7$- expres-
sion correlates with the immunoregulatory properties of the
respective cells, it was demonstrated here, that the suppres-
10 sor activity of the $CD3^+/CD14^+$ sub-population of the TAIC is
associated with a high expression of these three genes. This
is even more surprising when it is considered that these
markers have to date only been described for lymphocytes, but
never in cells of monocytic origin.

15

It was further shown that the direct co-culture of TAIC with
lymphocytes leads to a significantly higher amount of
$CD4^+/CD25^+$ lymphocytes as compared to indirect co-cultivation
and the cultivation of only lymphocytes. This supports the
20 assumption that also *in vivo* (i.e. in a patient) regulatory
T-cells are formed after administration of TAIC. These re-
sults are in conformity with the known immunoregulatory func-
tion of $CD4^+/CD25^+$ lymphocytes and with the fact, that the
contents of Foxp3-, CTLA-4-, and integrin $\alpha_E\beta_7$-mRNA in these
25 cells are significantly higher than in indirect co-cultivated
lymphocytes or in control lymphocytes.

53

Example 7

In vivo Induction of Transplant Tolerance by Lymphocytes co-cultured with TAIC *in vitro*

5   The results and conclusions presented in Example 6 were con-
firmed *in vivo* in an animal experiment. In this example ani-
mals in selected inbred combinations were injected with lym-
phocytes from the recipient which, over a period of 5 days,
were previously directly co-cultivated with TAIC from the do-
10 nor. Other animals were injected with lymphocytes from the re-
cipient, which were cultivated alone in medium as controls.

Animals, which have received autologous co-cultivated lympho-
cytes from the recipient prior to an allogeneic heart trans-
15 plantation developed donor specific tolerance, whereas control
animals, which have received naive non-cocultivated control
lymphocytes from the recipient acutely rejected the trans-
planted heart within 10 to 14 days.

20 This is also shown by flow cytometric determination of GM-7-
expression in the blood of patients postoperatively prior
(left Figure) and after (right Figure) injection of the lym-
phocytes co-cultivated with TAIC. The fraction of GM-7 bind-
ing cells raises from about 0.5 % prior to injection to about
25 21 % after injection indicating the development of regulatory
T-cells capable of binding GM-7.

These results indicate that the physical cell to cell interac-
tion between donor-TAIC and recipient-lymphocytes induces the
30 generation of regulatory T-cells, which, per se, are capable
of modifying the syngeneic immune system of the recipients
such, that potentially alloreactive T-cells are suppressed and
the organ rejection is thereby prevented.

54

Example 8

Use of the self-tolerance inducing cells (STIC) for the treatment of dextran sulphate sodium (DSS)-induced chronic colitis

Colitis can be chemically induced in mice by oral administration of dextran sulphate sodium via drinking water. Administration over a period of 7 days results in the development of acute colitis, repeated administration comprising at least four cycles DSS administration followed by 10 days normal water results in the development of chronic colitis resembling the human colitis ulcerosa.

This system is well established for immunological or molecular examinations [see e.g. Herfarth, H. et al. "Nuclear factor κB activity and intestinal inflammation in dextran sulphate sodium (DSS)-induced colitis in mice is suppressed by gliotoxin" Clin. Exp. Immunol. **120**, 59-65 (2000); Egger, B et al. "Mice lacking transforming growth factor α have an increased susceptibility to dextran sulfate-induced colitis" Gastroenterology **113**, 825-832 (1997)] and is used herein to examine the potential of STIC in the treatment of the chronic version of DSS-induced colitis resembling the human autoimmune colitis ulcerosa.

Normal female BALB/c mice (20 g each) were kept with unlimited access to water and standard chow. The mice received four cycles of water containing 5 % (w/v) dextran sulphate sodium (DSS; the solution is hereinafter referred to as DSS water) followed by untreated water according to the following scheme:

first cycle: day 1   to   7   DSS water (7 days);

55

```
                   day   8    to   17   normal water (10 days);
second cycle:      day  18    to   24   DSS water (7 days);
                   day  25    to   34   normal water (10 days);
third cycle:       day  35    to   41   DSS water (7 days);
                   day  42    to   51   normal water (10 days); and
fourth cycle:      day  52    to   58   DSS water (7 days).
```

After day 58 all mice show symptoms of chronic colitis which lasts for at least 2 months (Fig. 6 A and 6 B).

The mice were subsequently randomly assigned to four different groups:

group 1 (n=5):   on day +1 (day 59) after completion of the fourth cycle of being nourished with DSS water the mice received 62.5 international units heparin in 0.25 ml PBS intravenously (to prevent thrombosis) followed 30 sec later by administration of 5×10^6 STIC from an genetically identical donor mouse (see Example 2) intravenously in 1 ml PBS.

group 2 (n=7):   on day +7 (day 65) after completion of the fourth cycle of being nourished with DSS water the mice received 62.5 international units heparin in 0.25 ml PBS intravenously (to prevent thrombosis) followed 30 sec later by administration of 5×10^6 STIC from an genetically identical donor mouse (see Example 2) intravenously in 1 ml PBS.

group 3 (n=12): first control group undergoing the DSS treatment but did not receive any cell injection.

group 4 (n=6):   second control group undergoing the DSS treat-
                   ment; on day +1 (day 59) after completion of
                   the fourth cycle of being nourished with DSS
                   water the mice received 62.5 international
                   units heparin in 0.25 ml PBS intravenously (to
                   prevent thrombosis) followed 30 sec later by
                   administration of 5 × 10⁶ "control cells" from
                   an genetically identical donor mouse (see Ex-
                   ample 1) intravenously in 1 ml PBS ("Control
                   cells" are a mix of bone marrow cells, periph-
                   eral blood cells and spleen cells representing
                   the cells before culturing to produce the STIC
                   according to example 2, i.e. non-cultivated
                   cells obtained from the spleen of syngeneic
                   mice).

All mice are sacrificed on day 79, three weeks after comple-
tion of the fourth cycle of nourishment with DSS water.

In the course of the experiments the weight of the animals was
measured thrice a week during the DSS induction and during the
following three weeks. Changes in the body weight of the ani-
mals are expressed in percent (weight loss or gain) with ref-
erence to the weight of the mice at day 59, when they received
the cell therapy. Changes in the range of about 5 to 15 % are
considered to be significant.

The changes in the body weight of the mice in the course of
the 3 week period after the end of the DSS treatment are
shown in Fig. 7. As can bee seen, the administration of STIC
on day +1 (group 1 = □) leads to an adequate age-dependent
gain of weight, that can neither be found in untreated ani-

mals (group 3 = ▼), nor in animals treated with "control
cells" at day +1 (group 4 = ●) nor in animals treated with
STIC at day +7 (group 2 = ▲) during the progression of the
disease. The values are mean values obtained from 5 to 7 mice
5 per group, the standard deviation is always below ± 15 %.

In a further experiment, the colon tissue was histologically
stained with Hematoxylin &Eosin (H&E). The H&E staining was
carried out as described by Woods, A.E. and Ellis, R.C. (eds.)
10 (Laboratory Histopathology: A Complete Reference, vol. 1 & 2;
Churchill & Livingstone, 1994). The condition of the stained
mucosa was scored by two independently acting pathologists
that were blinded with respect to the experimental design ac-
cording to the following scheme:

15

    score 0   healthy unobtrusive finding;
    score 1   minimal colitis;
    score 2   moderate colitis;
    score 3   heavy colitis; and
20 score 4   ulcerative colitis accompanied by destruction of
               the whole mucosa.

The results of the scoring are shown in Figure 8. Three weeks
after completion of the fourth circle of feeding with DSS wa-
25 ter the control animals of group 3 (no cell injection) have
an average score of about 4, whereas the animals of group 1
(administration of STIC on day +1) or group 2 (administration
of STIC on day +7) have significantly reduced average scores
of about 1 (group 1) and about 1.5 (group 2), respectively.
30 The animals treated with "control cells" (group 4) have an av-
erage score of about 3, which is nearly as high as the score
of untreated mice (group 3).

These results are consistent with the findings of a his-
tological evaluation of the stained colon sections (H&E
staining, see above) as can be seen in Figure 6. This evalua-
tion is most critical for the determination of the effect of
5   the treatment with STIC. Fig. 6 A (magnification × 2.5) and
6B (magnification × 10) illustrate the condition of the colon
of an untreated animal of group 3 with a largely destroyed
mucosa and the surrounding tissues being heavily invaded by
inflammatory cells. These Figures show an advanced stadium of
10   colitis. Contrary to the advanced progression of the colitis
in untreated animals (Fig. 6A/B), the morphology of the mu-
cosa is maintained to a large extent in animals of group 1
that received STIC at day +1 (Fig. 6C (magnification × 2.5)
and 6D (magnification × 10)). Only minor signs of inflamma-
15   tion and destruction of the mucosa can be seen in these ani-
mals, but no invasion of the surrounding tissues. The colon
sections of a group 4 animal treated with "control cells" at
day +1 (Fig. 6E; magnification × 2.5) and of a group 2 animal
treated with STIC at day +7 (Fig. 6F; magnification × 2.5)
20   both show symptoms of advanced colitis with a largely de-
stroyed mucosa and the surrounding tissues being heavily in-
vaded by inflammatory cells similar to those seen in un-
treated animals (Fig. 6A/B).

25   The results of the above experiments show that STIC adminis-
tered at day +1 following the end of the DSS treatment for
the induction of colitis are capable of suppressing or
clearly alleviating symptoms of colitis. STIC-treated animals
do not significantly lose weight (Fig. 7), their histological
30   score is significantly reduced compared to untreated animals
(Fig. 8) and the overall condition of the mucosa of the colon
is almost normal as can be seen by histological staining of
colon sections (Fig. 6 C/D). STIC administered at day +7

59

(group 2) are not capable of treating the colitis developed
during the 7 day period prior to the administration of the
STIC. Although there is no reversion of the course of colitis
taking place, the progress of the disease is stopped as can
5   be seen from the lower histological score of a group 2 animal
compared to an untreated group 3 animal (Fig. 8). This phe-
nomena is specific for the model of DSS-induced colitis used
in this example and can not readily be transferred to other
conditions.

10

The mix of bone marrow cells, peripheral blood cells and
spleen cells representing the non-cultivated cells obtained
from the spleen of syngeneic mice are not feasible for the
treatment of colitis, since animals treated with these cells
15   (group 4) show symptoms as severe as untreated animals (Fig. 6
E/F; Fig. 7 and 8). This provides clear evidence that only the
STIC are capable of treating colitis and not other cells pres-
ent in the mix of cells the STIC develop from during culture.

20

Example 9
**Use of the self-tolerance inducing cells (STIC) for the treat-
ment of colitis induced in SCID mice by Transfer of $CD4^+CD62L^+$**
25   **lymphocytes**

The artificial induction of colitis in SCID (severe combined
immunodeficiency) mice is another approach for the analysis of
the STIC and their potential in the treatment of autoimmune
30   diseases.

SCID mice possess neither T nor B cells. Their immune system
can be reconstituted by transfer of a specific subpopulation
of thyroid cells. These cells, called $CD4^+CD62L^+$ or $CD62L^{high}$

cells repopulate the immune system but due to lack of control they also induce the development of spontaneous colitis with chronic inflammation. This model system is the so-called "CD62L$^+$/CD4$^+$ SCID transfer model of chronic experimental coli-

5   tis in mice" [see e.g. Mudter, J. et al. "A new model of chronic colitis in SCID mice induced by adoptive transfer of CD62L+ CD4+ T cells: Insights into the regulatory role of interleukin-6 on apoptosis" Pathobiology **70**, 170-176 (2002)] that allows more specific analysis of cell populations in-

10   volved in the development in colitis as an example of autoimmune diseases.

The model is used herein to examine the potential of STIC in the treatment of colitis induced by an deregulated immune sys-

15   tem. This model allows more mechanistic studies, but is considered to be the weaker system compared to the DSS model system (see Example 8 above) because the immune system is not fully repopulated.

20   SCID BALB/c mice (18 to 22 g each) receive an intraperitoneal injection of 1 × 10^6 CD4$^+$/CD62L-selectin^{high} T cells isolated from spleens of normal BALB/c mice using the "Macs" magnetic-bead cell-sorting system (Milteny Biotech, Germany) in PBS. The mice were kept with unlimited access to water and standard

25   chow.

Within 4 to 6 weeks after transfer of the CD4$^+$/CD62L-selectin^{high} T cells the mice develop colitis. The development of the colitis is determined by judgement of weight changes.

30

The mice were subsequently randomly assigned to three different groups:

61

group 1 (n=10): 6 weeks after initiation of the colitis induc-
tion by administration of the CD4$^+$/CD62L-
selectin^{high} T cells the mice received 62.5 in-
ternational units heparin in 0.25 ml PBS in-
travenously (to prevent thrombosis) followed
30 sec later by administration of 5×10^6 STIC
from an genetically identical donor mouse (see
Example 21) intravenously in 1 ml PBS.

group 2 (n=10): first control group receiving only the CD4$^+$/
CD62L-selectin^{high} T cells but did not receive
any further cell injection after 6 weeks.

group 3 (n=10): second control group receiving the CD4$^+$/CD62L-
selectin^{high} T cells. After 6 weeks the mice re-
ceived 62.5 international units heparin in
0.25 ml PBS intravenously (to prevent thrombo-
sis) followed 30 sec later by administration
of 5×10^6 "control cells" from an genetically
identical donor mouse (see Example 2) intrave-
nously in 1 ml PBS. "Control cells" are the
same as defined in example 8 (non-cultured mix
of bone marrow cells, peripheral blood cells
and spleen cells).

All rats are sacrificed 10 to 12 weeks after transfer of the
disease inducing T cells or when the control animals develop
signs of colitis judged by weight changes within the basic
control group 2.

Similar to the DSS model described in example 8 the body
weight of the animals was measured thrice a week during the
entire experimental period. Changes in the animal body weight

are expressed in percent (weight loss or gain) with reference
to the weight of the mice 6 weeks after the beginning of the
experiment when they receive the cell therapy. Again, changes
in the range of about 5 - 15 % are considered to be signifi-
5   cant.

The changes in the body weight of the mice in the course of
the entire experimental period are shown in Fig. 9. After 6
weeks mice of all groups are of almost the same body weight.
·10   While the administration of STIC after 6 weeks (group 1 = ◆)
afterwards leads to an adequate age-dependent gain of weight,
mice from the group of untreated animals (group 2 = ■) as
well as mice treated with "control cells" after 6 weeks
(group 3 = ▲) show a comparatively reduced gain of body
15   weight (group 2) or no gain at all (group 3) during the pro-
gression of the disease. The values are mean values obtained
from 6 mice per group, the standard deviation is always below
± 15 %.

20   Immediately after sacrifying the animals the colon length and
the spleen weight of these animals were determined. Both val-
ues allow an estimation of the extent of inflammation, but
are not very sensitive.

25   Figure 10 illustrates the results of the measurements of the
colon length (Fig. 10A) and the spleen weight (Fig. 10B). As
can be seen in this Figure, the colons of animals treated
with STIC (group 1) are significantly longer (about 11 cm)
and their spleen significantly smaller (about 50 mg) than
30   that of control animals. The control animals of group 2 have
shortened colons (about 10.3 cm) and enlarged spleens (about
100 mg) indicative for severe inflammation, whereas the ani-
mals receiving control cells (group 3) develop less severe

63

symptoms of colitis (colon lengths of about 10.6 cm and spleen weights of about 60 mg) compared to the control animals (group 2), but a more advanced colitis compared to the animals treated with the STIC (group 1).

5

Subsequently, in a further experiment, the colon tissue was histologically stained with Hematoxylin & Eosin (H&E staining; Woods, A.E. and Ellis, R.C. (eds.); Laboratory Histopathology: A Complete Reference, vol. 1 & 2; Churchill & Livingstone, 1994). As already described in Example 8, the condition of the mucosa was scored by two independently acting pathologists, that were blinded with respect to the experimental design. The scoring scheme for the mucosa was the same as in Example 8:

15

score 0   healthy unobtrusive finding;

score 1   minimal colitis;

score 2   moderate colitis;

score 3   heavy colitis; and

20   score 4   ulcerative colitis accompanied by destruction of
                the whole mucosa.

The average score is shown in Figure 11. Six weeks after transfer of the treatment the control animals of group 2 receiving no cell injection have an average score of about 3 indicating heavy colitis. The mice of group 1 receiving STIC and the mice of group 2 receiving control cells after 6 weeks have significantly reduced average scores of about 1.5 (indicating minimal colitis; group 1) and about 2.5 (indicating moderate colitis; group 2), respectively.

These results are again consistent with the findings of a histological evaluation of the colon sections stained with

64

H&E as can be seen in Figure 12 (magnification × 100). Fig.
12 A/B illustrate the condition of colons of animals of group
3 which remained untreated after induction of colitis with
CD62L^{high} T cells. Both examples show marked infiltration with

5   mononuclear cells and substantial loss of mucosal integrity,
crypt damage and infiltration of the submucosa and muscularis
propria layer. Injection of "control cells" (non-M-CSF and γ-
interferon-stimulated monocytes derived from blood, bone-
marrow and or spleen tissue) as described did not prevent

10 mononuclear cell infiltration and mucosal loss as can be seen
in Fig. 12C/D. Both specimen also show substantial submucosal
infiltration with lymphocytes, but the muscularis propria is
still intact. Administration of STIC after colitis induction
with CD62L^{high} T cells profoundly ameliorated the mucosal in-

15 tegrity (Fig. 12E/F). In colon sections of both specimen only
minor lymphocyte infiltration, no crypt loss and no damage to
the submucosa and muscularis propria layers within the ana-
lysed bowel segments can be seen.

20 Similar to the results obtained for the administration of
STIC for the treatment of dextran sulphate sodium (DSS)-
induced chronic colitis (see Example 8 above) it is shown
here using the CD62L$^+$/CD4$^+$ SCID transfer model of chronic ex-
perimental colitis in mice that STIC are capable of suppress-

25 ing or clearly alleviating symptoms of the induced colitis.
STIC-treated mice show an adequate age-dependent gain of
weight (Fig. 9), their colon is significantly longer (Fig.
10A) and their spleen weight significantly lower (Fig. 10B)
than that of mice of the control group suffering from severe

30 inflammation of the colon. Finally, the histological score of
STIC-treated mice is significantly lower compared to un-
treated animals (Fig. 11) and the histological analysis of

colon sections of mice treated with STIC shows only minor to no symptoms of colitis (Fig. 12).

5   Compared with the effect of the treatment of colitis with STIC the mix of bone marrow cells, peripheral blood cells and spleen cells representing the non-cultivated cells obtained from the spleen of syngeneic mice exhibits a significantly reduced efficacy, since animals treated with these cells (group 3) show more severe symptoms than that found in animals
10 treated with STIC (Fig. 9, 10A/B, 11 and 12). Contrary to the results obtained in Example 8 using the DSS model system, in the model of colitis induction with $CD62L^{high}$ cells the control cells are able to alleviate the symptoms to some extent, since the animals receiving the control cells exhibit less severe
15 symptoms compared to the control animals that do not receive any cells.

In accordance with the results of Example 8, this again provides clear evidence that the STIC of the invention are capa-
20 ble of treating autoimmune diseases.
